

Throughput-Delay Analysis of Random Linear Network Coding for Wireless Broadcasting

B. T. Swapna, Atilla Eryilmaz, and Ness B. Shroff

Abstract—In an unreliable single-hop broadcast network setting, we investigate the throughput and decoding-delay performance of random linear network coding as a function of the coding window size and the network size. Our model consists of a source transmitting packets of a single flow to a set of n users over independent time-correlated erasure channels. The source performs random linear network coding (RLNC) over k (coding window size) packets and broadcasts them to the users. We note that the broadcast throughput of RLNC must vanish with increasing n , for any fixed k . Hence, in contrast to other works in the literature, we investigate how the coding window size k must scale for increasing n . Our analysis reveals that the coding window size of $\Theta(\ln(n))$ represents a phase transition rate, below which the throughput converges to zero, and above which it converges to the broadcast capacity. Further, we characterize the asymptotic distribution of decoding delay and provide approximate expressions for the mean and variance of decoding delay for the scaling regime of $k = \omega(\ln(n))$. These asymptotic expressions reveal the impact of channel correlations on the throughput and delay performance of RLNC. We also show how our analysis can be extended to other rateless block coding schemes such as the LT codes. Finally, we comment on the extension of our results to the cases of dependent channels across users and asymmetric channel model.

Index Terms—Broadcast, Delay Analysis, Erasure Channel, Network Coding.

I. INTRODUCTION

We consider an important transmission scenario, occurring in many communication systems, whereby a source must broadcast common information to many users over wireless channels in a timely manner. Such a scenario occurs, for example, in a satellite or cellular network where a satellite or base station broadcasts a large file or streaming multimedia data to many users within their footprint over unreliable channels. Another example occurs in a multi-hop wireless network where each node broadcasts control information to all its immediate neighbors to coordinate medium access, power control, and routing operations. We note that such local sharing

of control information (such as queue-length or other pricing information) is common to many provably efficient network controllers (e.g. [2], [3], [4] etc.).

In this work, the essential components of such wireless broadcast systems are modeled through a transmitter broadcasting consecutive blocks of k data packets to n users over independent and identically fading time-correlated erasure channels with steady state erasure probability p . Assuming that the transmitter is infinitely backlogged, we consider transmission strategies that transfer the data in blocks of k packets, which include the class of block coding strategies. Among all such block transmission strategies, it has previously been shown (see [5]) that, for any fixed n and k , the Random Linear Network Coding (RLNC) strategy (see Section III for a detailed description) asymptotically¹ minimizes the number of transmissions required to complete the transfer of all k packets at all n users (also called the *block decoding delay*).

With this motivation, we focus on the scaling performance of RLNC as a function of k and n with respect to the following two key metrics: the (*broadcast*) *throughput*, defined as the data transfer rate to all users; and the (*broadcast*) *decoding delay*, defined as the amount of time spent between the start of a block transmission and its completion (i.e., successful decoding) at all the users.

It is not difficult to see that the (*broadcast*) *capacity* of such a collection of n erasure channels, for any n , is equal to $(1 - p)$ packets per time slot. Moreover, this maximum limit on the throughput can be arbitrarily closely achieved by encoding information into an arbitrarily large block size, k . Yet, this is not attractive since it leads to a decoding delay that diverges to infinity. In this work, we address the question of whether RLNC can achieve throughput arbitrarily close to the capacity while yielding acceptable decoding delay. The main contributions of this work are:

- We find that the broadcast throughput of RLNC must vanish for any fixed k as n tends to infinity. Using upper and lower bounds on the throughput and decoding-delay performance of the broadcast system, we show that a *phase transition* in the performance of our system occurs at the block length scaling rate² of $k = \Theta(\ln(n))$ with respect to the network size n . Specifically, we

¹This asymptotic is with respect to increasing field size over which the data packets are defined (see Section III).

²We use the standard order notation: $g(n) = o(f(n))$ implies $\lim_{n \rightarrow \infty} (g(n)/f(n)) = 0$; and $g(n) = \omega(f(n))$ implies $\lim_{n \rightarrow \infty} (g(n)/f(n)) = \infty$; and $g(n) = \Omega(f(n))$ implies $\lim_{n \rightarrow \infty} (g(n)/f(n)) \geq c$ for some constant $c > 0$; and $g(n) = \Theta(f(n))$ implies $c_1 \leq \lim_{n \rightarrow \infty} (g(n)/f(n)) \leq c_2$ for some constants $c_1 > 0$ and $c_2 > 0$.

show that if k increases slower than $\ln(n)$, then the broadcast throughput of RLNC converges to zero, and if k increases faster than $\ln(n)$, then the broadcast throughput of RLNC converges to the broadcast capacity of $(1 - p)$. In Section II, we shall note that the nature of this phase-transition is different from the previously observed phase-transition phenomenon in [6] due to a key difference in the scaling of k and the metric of focus.

- We characterize the asymptotic distribution of decoding delay and compute the mean and variance of decoding delay for the scaling regime of $k = \omega(\ln(n))$ using extreme value theory.
- We provide numerical results to substantiate our findings. Our results verify the phase transition with respect to the scaling rate and, not surprisingly, indicate that the rate of convergence to capacity can be increased by choosing a faster scaling of k with respect to n at the cost of higher decoding delay. Our results also show that the approximate expression for mean decoding delay obtained using extreme value theory is accurate even for small values of n .

These results collectively imply that RLNC can achieve throughput-delay tradeoff of $((1 - p), \Omega(\ln(n)))$. This is an attractive result as it indicates that as long as the coding block size scales super-logarithmically (i.e., very slowly) with the network size, the broadcast capacity is achievable with a simple policy such as RLNC.

The rest of the paper is organized as follows. In Section II, we overview some of the relevant work in this context. After introducing the main system components in Section III, we provide our throughput and delay analysis of RLNC for the case of time invariant erasure channels in Section IV. We present some numerical results to substantiate our findings in the Section V. In Section VI, we comment on three important extensions of our results - analysis of other rateless block coding schemes such as the LT codes, dependent channels across users, and asymmetric channel model. Finally, our conclusions are provided in Section VII.

II. RELATED WORK

Our model is similar to that considered in [5], [6], [7]. In [7], the authors quantify the reliability gain of RLNC for a fixed coding window size and show that RLNC significantly reduces the number of retransmissions in lossy networks compared to an end-to-end ARQ scheme. The delay performance gains of RLNC were observed in [5]. They show that, for a fixed coding window size k , the network coding capability can lead to significantly better delay performance as the system parameters (number of users) scale when compared to traditional transmission strategies without coding. More precisely, they show that, in the dense network setting where the number of receivers is large, the mean waiting time of scheduling relative to network coding for the same load scales quadratically with the coding window size.

Also, in a similar setup as in this paper, it has recently been shown in [6] that, for any given coding window size, there exists a phase transition with respect to decoding delay

such that there is a threshold on the number of transmissions below which the probability that a block of coded packets can be recovered by all the nodes in the network is close to zero. On the other hand, if the number of transmissions is slightly greater than the threshold, then the probability that every node in the network is able to reconstruct the block quickly approaches one.

All of the aforementioned works [5], [6], [7] study the gains of network coding as the system size grows while the coding window size is held constant. In particular, they show that the decoding delay of RLNC scales as $O(\ln(n))$ for a fixed coding window size as $n \rightarrow \infty$. However it can be seen that when the coding window size is held constant, the throughput of the system goes to zero as the system becomes large because each user receives a block of k packets in $O(\ln(n))$ time slots. Therefore, it is important to study the system when k is scaled as a function of n . In this paper, we investigate the decoding delay when the coding window size scales as a function of the network size. We observe that there is a phase transition with respect to broadcast throughput such that when the coding window size k scales asymptotically slower than $\ln(n)$, the broadcast throughput converges to zero. On the other hand, scaling k asymptotically faster than $\ln(n)$ leads to the broadcast throughput approaching $(1 - p)$. This behavior was first observed in [1] for a simple time-invariant channel model. In their preliminary investigations in [1], the authors prove this phase transition for an approximate system defined by appealing to the central limit theorem for *i.i.d* random variables. In this work, we investigate the throughput performance and explain the phase transition behavior for the more general case of a Markovian channel model. This phase transition is fundamentally different from that observed in [6] which relates to the decoding delay when k is fixed while the phase transition observed in our work relates to the nature of scaling of k as a function of network size n .

III. SYSTEM MODEL

In this work, we study the basic wireless broadcast scenario depicted in Figure 1 that models the characteristics of cellular or satellite systems and serves as the fundamental building block for more general networks.

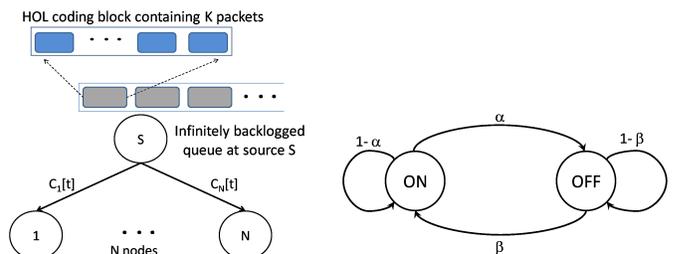

Fig. 1. A single source broadcasting Fig. 2. A time correlated erasure to n users over erasure channels with channel model. In state ON, the transmission probability of erasure, p in each time slot is successful while in state OFF, the transmission fails.

In particular, we consider a single source node, S , broadcasting an infinite backlog of common information to n users over

independent time-varying erasure channels. The data is encapsulated into *packets*, each represented as a vector of length l over a finite field \mathbb{F}_d . We assume a time-slotted operation of the system with $C_i[t] \in \{0, 1\}$ denoting the state of User i 's channel in slot t . A single packet may be broadcast in each time slot by the source and the transmission to the i^{th} user is successful only if $C_i[t] = 1$. Let $\mathbf{C}[t] = [C_1[t], \dots, C_n[t]]$ be the n -dimensional vector of channel states of all users in slot t . We refer to $\mathbf{C}[t]$ as the channel state of our system. $\mathbf{C}[t] \in \mathcal{S}^n$ where $\mathcal{S} = \{0, 1\}$. For simplicity, we assume that all channels are independent and identically distributed. Also, the source does not have any channel state information. We assume a time correlated erasure channel model between the source and each of the users that is defined next.

Definition 1 (Time Correlated Erasure Channel Model): In each time-slot, user i 's channel is in one of two states as shown in the Figure 2. When the channel is in the ON state, $C_i[t] = 1$ with probability 1 while in OFF state, $C_i[t] = 0$ with probability 1 . The state of the channel evolves as a Markov chain with transition probabilities α and β . Let p denote the steady state probability of an erasure over the channel. Then $p = \frac{\alpha}{\alpha + \beta}$. By setting $\alpha + \beta = 1$, we can obtain, as a special case, the time invariant erasure channel model, where $C_i[t] = 1$ with probability $1 - p$ and $C_i[t] = 0$ with probability p . Note that in the time invariant channel model, the channel state is *i.i.d* over time slots.

We consider the class of block coding strategies employed by the source, where data is transferred in blocks of k packets. Specifically, the source can start transmitting the next block only if the previous block is successfully transferred to all n receivers. Moreover, we focus on the Random Linear Network Coding (RLNC) strategy that is defined next.

Definition 2 (Random Linear Network Coding (RLNC)): In each time slot, the source transmits a random linear combination of the k packets in the Head-of-line (HOL) coding block (see Figure 1), i.e., the first block of k packets in the queue, with coefficients of combination chosen uniformly at random from the field \mathbb{F}_d . In what follows, we refer to k as the *coding window (or block) size* of RLNC.

Using random linear coding arguments [8], the probability that the original k packets can be decoded from any k encoded packets formed using the RLNC scheme is equal to $\left(1 - \frac{1}{d^k}\right) \left(1 - \frac{1}{d^{k-1}}\right) \dots \left(1 - \frac{1}{d}\right)$ which is bounded from below by $\left(1 - \frac{1}{d-1}\right)$. Therefore, for a large enough field size d , it is sufficient for the users to receive approximately k coded packets to be able to decode the block. Hence, we assume that, under the RLNC scheme, the source continues to transmit encoded packets of the current block until each user successfully receives k linear combinations. It has been shown in [9] that random linear network coding is capacity achieving for multicast connections in an unreliable network setting. That is, for k sufficiently large, under the coding scheme defined in Definition 2, the (broadcast) capacity of our system is $(1 - p)$. Next, we define the two metrics of interest in our analysis, namely throughput and decoding-delay.

Definition 3 ((Broadcast) Throughput): We let $R[t]$ denote the number of packets successfully served from the queue of the source in a total of t slots. Then, the (broadcast) throughput for a given n and k under RLNC scheme, denoted as $\eta(n, k)$, is the long-term average number of successfully transferred data packets to all n users. Hence, we have

$$\eta(n, k) = \lim_{t \rightarrow \infty} \frac{R[t]}{t}. \quad (1)$$

Definition 4 (Decoding-Delay): We let $Y_i^{(j)}$ denote the number of time slots it takes for the i^{th} user to decode the j^{th} block of k packets under the RLNC scheme. The decoding delay of the j^{th} block, for a given n and k , under the RLNC scheme, denoted as $U^{(j)}$, is the time required to transmit all packets of the head-of-line (HOL) block to all the users. Hence, we have

$$U^{(j)} = \max_{1 \leq i \leq n} Y_i^{(j)}. \quad (2)$$

Recall that the source transmits linear combinations of the current block until each user successfully receives k combinations. Then $Y_i^{(j)}$ is the time it takes for k successful transmissions on User i 's channel and can be written as the sum of durations between each of the k successful transmissions. Hence,

$$Y_i^{(j)} = \sum_{h=1}^k X_{ih}^{(j)}, \quad (3)$$

where $X_{ih}^{(j)}$ is the duration between the $(h-1)^{\text{th}}$ and h^{th} successful transmission on User i 's channel for the j^{th} coding block.

To understand the importance of scaling k as a function of n to guarantee a non-vanishing throughput, consider a simple time invariant channel model, i.e, let $C_i[t]$ be a Bernoulli random variable with p being the probability that $C_i[t] = 0$ in any given time slot t . Owing to the block transmission structure together with the independence of the channel states across time, the decoding delay of the block transmissions $\{U^{(j)}\}_{j \geq 1}$ are independent and identically distributed. This allows us to model the RLNC operation as a renewal process with renewals at the start of each coding block formation and $\{U^{(j)}\}_{j \geq 1}$ being the sequence of inter-renewal intervals. Let the random variable U be identically distributed as $\{U^{(j)}\}_{j \geq 1}$, and, $\mathbb{E}[U^{(j)}] = \mathbb{E}[U]$ for all j . Now, by defining a constant reward of k acquired in each renewal interval, we can utilize the main result in renewal theory for renewal reward processes (c.f. [10], Theorem 3.6.1, p. 133) to write:

$$\eta(n, k) = \lim_{t \rightarrow \infty} \frac{R[t]}{t} = \frac{k}{\mathbb{E}[U]}. \quad (4)$$

Under the time invariant erasure channel model, it is easy to see that for each i and j , $Y_i^{(j)}$ is the sum of k independent geometric random variable with success probability $(1 - p)$. The exact expression for $\mathbb{E}[U]$ is as follows,

$$\mathbb{E}[U] = k + \sum_{t=k}^{t=\infty} \left[1 - \left(\sum_{\tau=k}^{\tau=t} \binom{\tau-1}{k-1} p^{(\tau-k)} q^k \right)^n \right], \quad (5)$$

where $\binom{s}{m}$ gives the number of size m combinations of s elements and $q \triangleq (1 - p)$.

The exact expression for $\mathbb{E}[U]$ is difficult to simplify further. However, as we show later in Lemmas 1 and 4, $\mathbb{E}[U]$ is $\Theta(\ln(n))$, since it is the maximum of n *i.i.d* random variables. Thus, for any fixed k , $\eta(n, k)$ in (4) goes to zero as n approaches ∞ .

In the next section, we provide throughput and delay analysis of RLNC for the time-correlated channel model. By identifying a suitable renewal process with reward $R(t)$, we express throughput in terms of $\mathbb{E}[U^{(j)}]$ and k using the main result in renewal theory for renewal-reward processes [10]. However, explicit characterization of $\mathbb{E}[U^{(j)}]$ is difficult. Instead, we derive upper and lower bounds on $\mathbb{E}[U^{(j)}]$ which enable us to understand the scaling of k as a function of n to guarantee a non-vanishing throughput. Further, we compute the asymptotic approximation for the mean and variance of $U^{(j)}$ when k scales faster than $\ln(n)$.

IV. ANALYSIS OF RLNC FOR TIME CORRELATED ERASURE CHANNELS

Under the time correlated channel model (when $\alpha + \beta \neq 1$ in Definition 1), the RLNC operation is not a renewal process after each coding block transmission and (4) is not valid. Hence, in order to express the broadcast throughput in terms of the decoding delay, we model the RLNC operation over time correlated channels as a semi-Markov process and identify a suitable renewal-reward process. By deriving upper and lower bounds on the decoding delay and hence, the throughput, we show that a phase transition in the throughput performance of our system occurs at the block-length scaling rate of $k = \Theta(\ln(n))$. This result is summarized in the following theorem:

Theorem 1: Under the RLNC scheme, the broadcast throughput $\eta(n, k)$ of our system, when $\alpha, \beta > 0$, and $\alpha + \beta \neq 2$, can be characterized as follows,

a) If $k = o(\ln(n))$, then

$$\lim_{n \rightarrow \infty} \eta(n, k) = 0. \quad (6)$$

b) If $k = \omega(\ln(n))$, then

$$\lim_{n \rightarrow \infty} \eta(n, k) = 1 - p. \quad (7)$$

c) Furthermore, if $k = \Theta(\ln(n))$, then

$$\liminf_{n \rightarrow \infty} \eta(n, k) \geq r(1 - p), \quad (8)$$

where $0 < r < 1$ is given in (25).

Remark 1: When k increases, every linear combination broadcast by the source could potentially bring some new information for every user in the system, and we expect the users to decode the entire block at nearly the same time, i.e., idle waiting time of each user for the beginning of next block transmission is reduced. Hence, although the decoding delay is large for large k , by identifying the right scaling of k as a function of n , the throughput could potentially reach $(1 - p)$. This scaling is identified in Part (b) of Theorem 1.

In what follows, we develop the mathematical model required to prove the above result. We also characterize the asymptotic distribution of the decoding delay for the scaling regime

of $k = \omega(\ln(n))$ and derive approximate expressions for the mean and variance of the decoding delay using extreme value theory. These expressions reveal the effect of channel correlation on the throughput and delay performance of RLNC.

A. Throughput and Delay Analysis

Let $T^{(j)} \in \mathbb{Z}^+$ denote the time slot of the completion of the j^{th} block transmission. Set $T^{(0)} = 0$. Let the random variable $\mathbf{E}^{(j)} \in \mathcal{S}^n$ denote the channel state of the system in time slot $T^{(j)}$, i.e., at the end of the j^{th} block transmission. Consider the stochastic process $\{\mathbf{E}[t], t \geq 0\}$, where, for each $j \geq 1$, $\mathbf{E}[t] = \mathbf{E}^{(j-1)}$ for t in the interval $T^{(j-1)} \leq t < T^{(j)}$. Note that each user's channel evolves according to the Markov chain shown in Figure 2 independently of other users. Hence, the stochastic process, $\{\mathbf{E}[t], t \geq 0\}$, is a semi-Markov process where the state transitions occur at the end of each block transmission. Let $\mathbf{E}^{(0)} = \mathbf{1}$, i.e., the process starts with all the user channels being ON. We have that $U^{(j)} = T^{(j)} - T^{(j-1)}$, $j \geq 1$ is the (holding) time between successive state transitions. Note that $U^{(j)}$ is the decoding delay of the j^{th} block transmission and is a non-negative random variable that depends only on the state of the stochastic process at times $T^{(j)}$, and $T^{(j-1)}$. The embedded Markov chain $\{\mathbf{E}^{(j)}, j \geq 0\}$ is an irreducible finite state (2^n states) Markov chain when $\alpha \neq 0$ and $\beta \neq 0$. Also, the embedded Markov chain is aperiodic when $\alpha \neq 1$ or $\beta \neq 1$.³ Let the random variable $\mathbf{B}^{(j)} \in \mathcal{S}^n$ denote the channel state of the system in the time slot $T^{(j-1)} + 1$, i.e., at the beginning of j^{th} block transmission.

The time epochs of return to the channel state $\mathbf{s} = \mathbf{1}$ in the semi-Markov process form a renewal process. The source completes transmission of a random number of blocks in each inter-renewal interval. Let the random variable W denote the length of one such inter-renewal interval. Let M denote the random number of block transmissions completed in this interval. Therefore, we have the identity $W = \sum_{j=1}^M U^{(j)}$.

Figure 3 provides a schematic of the notation described so far.

Now, M represents the number of transitions in the embedded Markov chain between consecutive visits to state $\mathbf{1}$. Since the embedded Markov chain is an irreducible aperiodic finite state Markov chain, we have that the steady state probabilities of each state \mathbf{s} in the embedded chain, $\Pi_{\mathbf{s}}$ is strictly positive. Hence $\mathbb{E}[M] = \frac{1}{\Pi_{\mathbf{1}}} < \infty$ [10].

Since $\mathbb{E}[M] < \infty$, by defining a reward of 1 for each packet transmitted in a renewal interval, we can utilize the main result from renewal theory (cf. [10], Theorem 3.6.1, p. 133) to write:

$$\eta(n, k) = \lim_{t \rightarrow \infty} \frac{R(t)}{t} = \frac{k\mathbb{E}[M]}{\mathbb{E}[W]}. \quad (9)$$

The random variable W depends on the channel state of the system at the beginning of each of the M block transmissions. Also, owing to the time correlated channel process, the random

³The cases when 1) $\alpha = \beta = 1$ and 2) $\alpha = 0$ or $\beta = 0$ are trivial since the channel becomes deterministic within a finite expected number of time-slots.

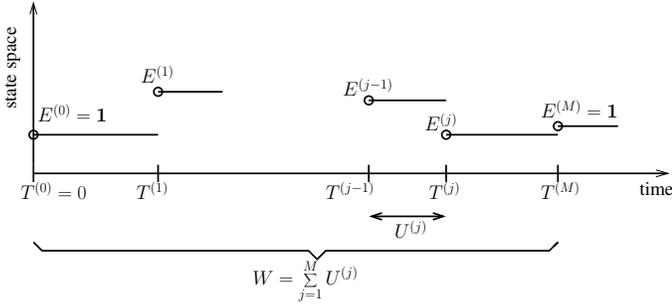

Fig. 3. Schematic of the semi-Markov process $\{\mathbf{E}[t], t \geq 0\}$. State transitions occur at $T^{(j)}$ which is the time slot of completion of the j^{th} block transmission. $\mathbf{E}^{(j)} \in \mathcal{S}^n$ is the channel state of the system in time slot $T^{(j)}$. The stochastic process $\mathbf{E}[t] = \mathbf{E}^{(j-1)}$ for $T^{(j-1)} \leq t < T^{(j)}$. The time epochs of return to channel state $\mathbf{1}$ form a renewal process and W is the length of one such inter-renewal interval.

variables $\{U^{(j)}\}_{j=1}^M$ are not *i.i.d.* An explicit characterization of $\mathbb{E}[W]$ in terms of $\{U^{(j)}\}$ is, therefore, difficult. Instead, we obtain upper and lower bounds on $\mathbb{E}[W]$. Recall that $U^{(j)}$, $j \geq 1$ is the decoding delay of the j^{th} block. Now using (2) and (3), we have $U^{(j)} = \max_{1 \leq i \leq n} \sum_{h=1}^k X_{ih}^{(j)}$. We can bound $U^{(j)}$, for $k \geq 2$, as follows,

$$\begin{aligned} \max_{1 \leq i \leq n} X_{i2}^{(j)} \leq U^{(j)} &\leq \max_{1 \leq i \leq n} X_{i1}^{(j)} \\ &+ \max_{1 \leq i \leq n} \left(X_{i2}^{(j)} + \dots + X_{ik}^{(j)} \right) \text{ a.s.} \end{aligned} \quad (10)$$

The lower bound in the above equation is obtained by using the fact that $X_{ih}^{(j)} \geq 0$. The upper bound is due to the following simple identity: If a_1, a_2, b_1, b_2 are any four non-negative real numbers, then $\max(a_1 + a_2, b_1 + b_2) \leq \max(a_1, b_1) + \max(a_2, b_2)$. Note that, for all $h \geq 2$, $X_{ih}^{(j)}$ is the number of time-slots between the $(h-1)^{\text{th}}$ and h^{th} successful transmission given that the channel state of User i in the time slot of reception of $(h-1)^{\text{th}}$ linear combination is ON. Therefore, the random variables $\{X_{ih}^{(j)}\}$ are *i.i.d.* for all $i = 1, \dots, n, \forall j \geq 1, \forall h \geq 2$. We also have that, for all $j \geq 1$ and $h \geq 2$, $X_{ih}^{(j)}$ is independent of $\mathbf{E}^{(1)}, \dots, \mathbf{E}^{(j-1)}$. Also, note that $X_{i1}^{(j)}$, $j \geq 1$ is not independent of $\mathbf{E}^{(j-1)}$. Let \mathcal{F}_j be the smallest σ -field of events containing the σ -fields generated by the random variables $\{X_{ih}^{(1)}, \dots, X_{ih}^{(j)}, i = 1, \dots, n, h = 1, \dots, k\}$ and $\mathbf{E}^{(1)}, \dots, \mathbf{E}^{(j)}$. Then, M is a stopping time with respect to the filtration $\{\mathcal{F}_j\}$.

Now, the identity $W = \sum_{j=1}^M U^{(j)}$ along with (10) enables us to bound $\mathbb{E}[W]$ as follows,

$$\mathbb{E}[W] \geq \mathbb{E} \left[\sum_{j=1}^M \max_{1 \leq i \leq n} X_{i2}^{(j)} \right] \quad (11)$$

$$\begin{aligned} \mathbb{E}[W] &\leq \mathbb{E} \left[\sum_{j=1}^M \max_{1 \leq i \leq n} X_{i1}^{(j)} \right] \\ &+ \mathbb{E} \left[\sum_{j=1}^M \max_{1 \leq i \leq n} \left(X_{i2}^{(j)} + \dots + X_{ik}^{(j)} \right) \right] \end{aligned} \quad (12)$$

To prove Theorem 1, we further bound the lower and upper bounds on $\mathbb{E}[W]$ in (11) and (12), respectively. First, we state a useful lemma [11]:

Lemma 1: (From [11], p. 7) Let $\chi_i, i = 1, 2, \dots, n$ be identically distributed and possibly correlated random variables. Then for any $\tau > 0$, we have that

$$\mathbb{E} \left[\max_{1 \leq i \leq n} \chi_i \right] \leq \frac{1}{\tau} \left(\ln(n) + \ln(\mathbb{E}[e^{\tau \chi_1}]) \right) \quad (13)$$

Note that the above bound is useful only when τ lies within the radius of convergence of the moment generating function (m.g.f) of χ_1 .

Next, we state a few lemmas that will be useful in the proof of Theorem 1. The proofs of these lemmas are given in Appendix I. Recall that $\mathbf{B}^{(j)} \in \mathcal{S}^n$ denotes the channel state of the system at beginning of j^{th} block transmission. For any fixed n , $|\mathcal{S}^n|$ is finite. Hence, $\max_{\mathbf{s} \in \mathcal{S}^n} \mathbb{E} \left[\max_{1 \leq i \leq n} X_{ih}^{(j)} | \mathbf{B}^{(j)} = \mathbf{s} \right]$ exists and can be bounded as follows,

Lemma 2: There exist constants μ_0 and τ_0 such that, for all j and h ,

$$\max_{\mathbf{s} \in \mathcal{S}^n} \mathbb{E} \left[\max_{1 \leq i \leq n} X_{ih}^{(j)} | \mathbf{B}^{(j)} = \mathbf{s} \right] \leq \frac{1}{\tau_0} (\ln(n) + \mu_0).$$

Also, $\mathbb{E} \left[\max_{1 \leq i \leq n} X_{ih}^{(j)} \right] < \infty$ for any $j, h \in \{1, \dots, k\}$.

Proof: See Appendix I ■

In the next lemma, we find an upper bound on the expected value of $\sum_{j=1}^M \max_{1 \leq i \leq n} X_{i1}^{(j)}$:

Lemma 3: Let $\mu = \frac{1}{\tau_0} (\ln(n) + \ln(\mu_0))$ where τ_0 and μ_0 are defined in the previous lemma. Then,

$$\mathbb{E} \left[\sum_{j=1}^M \max_{1 \leq i \leq n} X_{i1}^{(j)} \right] \leq \mathbb{E}[M] \mu. \quad (14)$$

Proof: See Appendix I ■

Next, we find a lower bound on the expected value of $\max_{1 \leq i \leq n} X_{i2}^{(j)}$:

Lemma 4: Let $\lambda = -\ln(1 - \beta)$. Then, for all j , we have

$$\mathbb{E} \left[\max_{1 \leq i \leq n} X_{i2}^{(j)} \right] \geq 1 + \frac{\alpha}{\lambda} [\ln(n) + \gamma], \quad (15)$$

where γ is the Euler's constant.

Proof: See Appendix I ■

Next, we prove Theorem 1 using the above lemmas and Wald's first equation to bound the lower and upper bounds in (11) and (12), respectively.

Proof: (Proof of the Theorem 1)

Proof of (a): First, we prove that $k = o(\ln(n))$ leads to

a vanishing throughput. As mentioned in Lemma 3, M is a stopping time with respect to the filtration $\{\mathcal{F}_j\}$. We have that $\{\max_{1 \leq i \leq n} X_{i2}^{(j)}\}_{j \geq 1}$ are identically distributed and have a finite mean. Also, $\max_{1 \leq i \leq n} X_{i2}^{(j)}$ is independent of \mathcal{F}_{j-1} . Thus, using Wald's first equation and Lemma 4, we can lower bound $\mathbb{E}[W]$ (cf. (11)) as follows,

$$\begin{aligned} \mathbb{E}[W] &\geq \mathbb{E}[M] \mathbb{E} \left[\max_{1 \leq i \leq n} X_{i2}^{(1)} \right] \\ &\geq \mathbb{E}[M] \left(1 + \frac{\alpha}{\lambda} [\ln(n) + \gamma] \right). \end{aligned}$$

Consequently, using (9), we can bound the throughput from above as follows,

$$\eta(n, k) \leq \frac{k \mathbb{E}[M] \lambda}{\mathbb{E}[M] (\lambda + \alpha [\ln(n) + \gamma])} \quad (16)$$

$$= \frac{k \lambda}{\lambda + \alpha [\ln(n) + \gamma]}. \quad (17)$$

Clearly, when $k = o(\ln(n))$, the upper bound, and hence, $\eta(n, k)$ decreases to zero, as $n \rightarrow \infty$.

Proof of (b) : Next, we consider the case when $k = \omega(\ln(n))$. We let $k = f(n) \ln(n) + 1$ for some function $f(n) > 0$ such that $\lim_{n \rightarrow \infty} f(n) = \infty$. Let $\hat{Y}_i^{(j)} = X_{i2}^{(j)} + \dots + X_{ik}^{(j)}$. Let $\hat{\mu}$ and $\hat{\sigma}^2$ be the mean and variance of $\hat{Y}_i^{(j)}$. Then,

$$\begin{aligned} \hat{\mu} &= (k-1) \left(1 + \frac{\alpha}{\beta} \right) = (k-1) \frac{1}{1-p}, \\ \hat{\sigma}^2 &= \frac{(k-1) \alpha [2 - (\alpha + \beta)]}{\beta^2}. \end{aligned} \quad (18)$$

As mentioned in Lemma 3, M is a stopping time with respect to the filtration $\{\mathcal{F}_j\}$. We have that $\{\max_{1 \leq i \leq n} \hat{Y}_i^{(j)}\}_{j \geq 1}$ are identically distributed and have a finite mean. Also, $\max_{1 \leq i \leq n} \hat{Y}_i^{(j)}$ is independent of \mathcal{F}_{j-1} . Using Wald's first equation and Lemma 3, we can rewrite (12) as follows,

$$\begin{aligned} \mathbb{E}[W] &\leq \mathbb{E} \left[\sum_{j=1}^M \max_{1 \leq i \leq n} X_{i1}^{(j)} \right] + \mathbb{E}[M] \hat{\mu} \\ &\quad + \hat{\sigma} \mathbb{E} \left[\sum_{j=1}^M \max_{1 \leq i \leq n} \frac{\hat{Y}_i^{(j)} - \hat{\mu}}{\hat{\sigma}} \right] \\ &\leq \mathbb{E}[M] \left(\mu + \hat{\mu} + \hat{\sigma} \mathbb{E} \left[\max_{1 \leq i \leq n} \frac{\hat{Y}_i^{(j)} - \hat{\mu}}{\hat{\sigma}} \right] \right). \end{aligned} \quad (19)$$

Now, using Lemma 1, for $0 < \tau \leq \hat{\sigma} \ln(\frac{1}{1-\beta})$, we have the following upper bound,

$$\begin{aligned} &\mathbb{E} \left[\max_{1 \leq i \leq n} \frac{\hat{Y}_i^{(j)} - \hat{\mu}}{\hat{\sigma}} \right] \\ &\leq \frac{1}{\tau} \left(\ln(n) + \ln \left(\mathbb{E} \left[\exp \left(\tau \frac{\hat{Y}_i^{(j)} - \hat{\mu}}{\hat{\sigma}} \right) \right] \right) \right) \end{aligned}$$

Define $\phi(n)$ as follows,

$$\begin{aligned} \phi(n) &= (1-p) \left(\mu + \hat{\mu} + \frac{\hat{\sigma}}{\tau} \ln(n) \right. \\ &\quad \left. + \frac{\hat{\sigma}}{\tau} \ln \left(\mathbb{E} \left[\exp \left(\tau \frac{\hat{Y}_i^{(j)} - \hat{\mu}}{\hat{\sigma}} \right) \right] \right) \right). \end{aligned} \quad (20)$$

Using (19) and (20), we can bound $\mathbb{E}[W]$ and $\eta(n, k)$ as follows,

$$\begin{aligned} \mathbb{E}[W] &\leq \mathbb{E}[M] \frac{\phi(n)}{1-p}, \\ \eta(n, k) &= \frac{k \mathbb{E}[M]}{\mathbb{E}[W]} \geq \frac{(1-p)(f(n) \ln(n) + 1)}{\phi(n)}. \end{aligned} \quad (21)$$

Next, choose $\tau = b \sqrt{\ln(n)}$ where b is a constant such that $0 < \tau \leq \hat{\sigma} \ln(\frac{1}{1-\beta})$. For such a τ ,

$$\begin{aligned} \mathbb{E} \left[\exp \left(\tau \frac{\hat{Y}_i^{(j)} - \hat{\mu}}{\hat{\sigma}} \right) \right] &= e^{-\tau \hat{\mu} / \hat{\sigma}} \left(\mathbb{E} \left[\frac{\tau X_{i2}^{(j)}}{\hat{\sigma}} \right] \right)^{k-1} \\ &= e^{-\tau \hat{\mu} / \hat{\sigma}} \left((1-\alpha) e^{\tau / \hat{\sigma}} + \sum_{u=2}^{\infty} \alpha \beta (1-\beta)^{u-2} e^{\tau u / \hat{\sigma}} \right)^{k-1} \\ &= e^{-\tau \hat{\mu} / \hat{\sigma}} \left((1-\alpha) e^{\tau / \hat{\sigma}} + \frac{\alpha \beta e^{2\tau / \hat{\sigma}}}{1 - e^{\tau / \hat{\sigma}} (1-\beta)} \right)^{k-1} \\ &= e^{-\tau \hat{\mu} / \hat{\sigma}} \left(\frac{e^{\tau / \hat{\sigma}} [1 - \alpha (1 - e^{\tau / \hat{\sigma}})] - e^{\tau / \hat{\sigma}} (1-\beta)}{1 - e^{\tau / \hat{\sigma}} (1-\beta)} \right)^{k-1} \\ &= r(n)^{f(n) \ln(n)}, \end{aligned} \quad (22)$$

where $r(n)$ is obtained by substituting for $\hat{\mu}$ and $\hat{\sigma}$ from (18) and using $\tau = b \sqrt{\ln(n)}$, and $k-1 = f(n) \ln(n)$ in (22) above. The expression for $r(n)$ is given as follows

$$r(n) = \left(\frac{e^{\frac{d_1}{\sqrt{f(n)}}} \left[1 - \alpha \left(1 - e^{\frac{d_2}{\sqrt{f(n)}}} \right) - e^{\frac{d_2}{\sqrt{f(n)}}} (1-\beta) \right]}{1 - e^{\frac{d_2}{\sqrt{f(n)}}} (1-\beta)} \right),$$

$$\text{with } d_1 = \frac{-b\sqrt{\alpha}}{\sqrt{2-\alpha-\beta}} \text{ and } d_2 = \frac{b\beta}{\sqrt{\alpha(2-\alpha-\beta)}}.$$

Substituting (18), (23), $\tau = b \sqrt{\ln(n)}$, and $\mu = \frac{1}{\tau_0} (\ln(n) + \ln(\mu_0))$, in the expression for $\phi(n)$ in (20), we get

$$\begin{aligned} \phi(n) &= \frac{1-p}{\tau_0} \ln(n \mu_0) + f(n) \ln(n) \\ &\quad + d_3 (1-p) \sqrt{f(n)} \ln(n) (1 + f(n) \ln(r(n))), \end{aligned} \quad (24)$$

where $d_3 = \frac{\sqrt{\alpha[2-(\alpha+\beta)]}}{b\beta}$. Since, $f(n) \rightarrow \infty$, as $n \rightarrow \infty$, we

have $r(n) \rightarrow 1$ as $n \rightarrow \infty$. Then,

$$\begin{aligned}
& \lim_{n \rightarrow \infty} \frac{\phi(n)}{f(n) \ln(n) + 1} - 1 \\
&= d_3 \lim_{n \rightarrow \infty} \sqrt{f(n)} \ln(r(n)) \\
&= d_3 \lim_{n \rightarrow \infty} \sqrt{f(n)} (1 - r(n)) \ln(1 - (1 - r(n)))^{\frac{1}{1-r(n)}} \\
&= -d_3 \lim_{n \rightarrow \infty} \sqrt{f(n)} (1 - r(n)) \quad (i) \\
&= \frac{-d_3}{\beta} \lim_{n \rightarrow \infty} \sqrt{f(n)} \left(1 - (1 - \beta) e^{\frac{d_2}{\sqrt{f(n)}}} \right. \\
&\quad \left. - e^{\frac{d_1}{\sqrt{f(n)}}} \left[1 - \alpha \left(1 - e^{\frac{d_2}{\sqrt{f(n)}}} \right) - (1 - \beta) e^{\frac{d_2}{\sqrt{f(n)}}} \right] \right) \\
&= 0, \quad (ii)
\end{aligned}$$

where (i) follows by noting that $(1 - (1 - r(n)))^{\frac{1}{1-r(n)}} \rightarrow e^{-1}$ as $n \rightarrow \infty$ and (ii) follows by *L'Hôpital's* rule. Hence, from (21) and the fact that $\eta(n, k) \leq (1 - p)$, we see that under the scaling regime of $k = \omega(\ln(n))$, we have $\eta(n, k) \rightarrow (1 - p)$ as $n \rightarrow \infty$.

Proof of (c): Finally, consider the case when $k = \Theta(\ln(n))$. This is achieved by letting $f(n) = \hat{b}$ for some constant \hat{b} independent of n in the above analysis. Then, $r(n)$ is a constant independent of n and we denote $\rho = r(n)$ in this case. Now, using (24), we can write,

$$\begin{aligned}
& \lim_{n \rightarrow \infty} \frac{\phi(n)}{f(n) \ln(n) + 1} \\
&= 1 + \frac{1 - p}{\tau_0 \hat{b}} + \frac{\sqrt{\alpha[2 - (\alpha + \beta)]}}{b\beta\sqrt{\hat{b}}} (1 + \hat{b} \ln(\rho)) \\
&= \Delta := \frac{1}{r} < \infty \quad (25)
\end{aligned}$$

where $\Delta \geq 1$, because we know that $\eta(n, k) \leq (1 - p)$ and hence, $\frac{\phi(n)}{f(n) \ln(n) + 1} \geq 1$. Now we can see, from (21), that a constant fraction $0 < r = \frac{1}{\Delta} \leq 1$ of the capacity is guaranteed, hence proving (c). ■

B. Computing the Mean and Variance of Decoding Delay

In Theorem 1, we showed that it is necessary to scale k at least as $\ln(n)$ to guarantee a non-vanishing broadcast throughput. Next, we aim to obtain an accurate characterization of the decoding delay, $U^{(j)}$ in the scaling regime of $k = \omega(\ln(n))$. Recall that $U^{(j)} = \max_{1 \leq i \leq n} Y_i^{(j)}$. In what follows, we drop the superscript (j) and let U denote the decoding delay of our system under the RLNC scheme.

First consider the case of time-invariant channel model. We see that, for each j , $Y_i^{(j)}$ in (3) is the sum of *i.i.d* random variables. By appealing to the Central Limit Theorem, we know that, after suitable standardization, $Y_i^{(j)}$ converges in distribution to a standard normal random variable as $k \rightarrow \infty$. It is also well-known that, the distribution of the maximum of n normal random variables, after suitable standardization, converges weakly to the Gumbel distribution [12] as $n \rightarrow \infty$. Therefore, we expect the decoding delay, U , to converge in distribution to the Gumbel distribution, after suitable standardization, as $n \rightarrow \infty$. This is shown to be true in [13] for the

general case of maxima of sum of *i.i.d* random variables. We summarize the result for our setting in the following theorem,

Proposition 1: (cf. [13], Proposition 2, p. 961) Let $\mu(k) = \frac{k}{1-p}$ and $\sigma^2(k) = k \frac{p}{(1-p)^2}$. When $k = \omega(\ln(n))$, we have

$$\lim_{n \rightarrow \infty} \mathbb{P} \left(\frac{U - \mu(k)}{\sigma(k)} \leq a_n x + b_n \right) = \exp(-e^{-x}),$$

where $b_n \sim \sqrt{2 \ln(n)} - \frac{\ln(\ln(n)) + \ln(4\pi)}{2\sqrt{2 \ln(n)}}$ and $a_n := \frac{1}{b_n} \sim \frac{1}{\sqrt{2 \ln(n)}}$ as $n \rightarrow \infty$.

In Section V, we show the above convergence in distribution using numerical simulations (cf. Figure 10). In general, convergence in distribution does not imply convergence in moments. However, for the case of distributions belonging to the domain of attraction of the Gumbel distribution, convergence of moments holds true [14]. Let $\tilde{U} = \frac{U - \mu(k)}{\sigma(k)}$. Then, $\forall r \geq 0$, we have,

$$\lim_{n \rightarrow \infty} \mathbb{E} \left[\frac{\tilde{U} - b_n}{a_n} \right]^r = \int_{-\infty}^{\infty} x^r d \exp(-e^{-x}). \quad (26)$$

Now, $\int_{-\infty}^{\infty} x d \exp(-e^{-x}) = \gamma$ where γ is the Euler's constant and $\int_{-\infty}^{\infty} x^2 d \exp(-e^{-x}) = \frac{\pi^2}{6} + \gamma^2$. This enables to write the following approximate expressions for the mean and variance of decoding delay, when n is large,

$$\mathbb{E}[U] \approx \frac{k}{1-p} + \frac{\sqrt{kp}}{1-p} \left(\sqrt{2 \ln(n)} + \gamma \frac{1}{\sqrt{2 \ln(n)}} \right), \quad (27)$$

$$\text{var}[U] \approx \frac{kp\pi^2}{12(1-p)^2 \ln(n)}. \quad (28)$$

By using (27) in (4), we can verify that when $k = \omega(\ln(n))$, the throughput converges to $1 - p$ as $n \rightarrow \infty$. In Section V, using simulations (cf. Figure 6, 7), we show that the above approximate expressions are accurate even for small values of n .

In [6], the authors show that, when k is fixed,

$$\lim_{n \rightarrow \infty} \mathbb{P} \left(U \leq \tilde{a}_n x + \tilde{b}_n \right) = \exp(-e^{-x}), \quad (29)$$

where $\tilde{a}_n = \frac{-1}{\ln(p)}$ and $\tilde{b}_n \sim \ln(n)$ as $n \rightarrow \infty$.

Now, since \tilde{a}_n is a constant, the asymptotic distribution of the decoding delay, U , is concentrated around the point \tilde{b}_n with a fixed variance for all n and hence, there exists a phase transition with respect to the decoding delay, U , such that there exists a threshold on the number of transmissions below which the probability that a block of coded packets can be recovered by all the nodes in the network is close to zero. On the other hand, if the number of transmissions is slightly greater than the threshold, then the probability that every node in the network is able to reconstruct the block quickly approaches one. However, when $k = \omega(\ln(n))$, $\text{var}[U]$ in (28) increases with n and the phase transition phenomenon observed in [6] becomes less evident.

For the case of correlated channels, we analyze the decoding delay for the case when the channel state of the system is

$\mathbf{s} = \mathbf{1}$ in the time slot prior to the beginning of the new block transmission. Let the random variable U denote this decoding delay as well. In this case too, the decoding delay for each user can be written as a sum of *i.i.d* random variables. Hence, we have a similar proposition as Proposition 1. We can write the approximate expressions for mean decoding delay and variance of decoding delay, when n is large, for both the channel models, concisely, as follows,

$$\mathbb{E}[U] \approx \frac{k}{1-p} + \frac{\sqrt{d_4 k p}}{1-p} \left(\sqrt{2 \ln(n)} + \frac{\gamma}{\sqrt{2 \ln(n)}} \right), \quad (30)$$

$$\text{var}[U] \approx \frac{k p \pi^2 d_4}{12(1-p)^2 \ln(n)}, \quad (31)$$

where $d_4 = \left(\frac{2}{\alpha + \beta} - 1 \right)$. Note that the above expressions are the same as (27) and (28) for the time invariant channel if we choose $\alpha + \beta = 1$ and $p = \frac{\alpha}{\alpha + \beta}$. Although (30) is derived under the assumption that the channel state of the system before the beginning of the block transmission is $\mathbf{s} = \mathbf{1}$, we show, using simulations (cf. Figure 8, 9) in Section V, it is an accurate upper bound on the decoding delay performance of the actual system.

We can observe an interesting fact from expression (30): we see that the mean decoding delay decreases as the channel becomes more negatively correlated, i.e., $1 < \alpha + \beta \rightarrow 2$ and increases as the channel becomes more positively correlated, i.e., $\alpha + \beta < 1$, $\alpha + \beta \rightarrow 0$. The holding time of any state is longer when the channel is positively correlated and hence, the channel remains in a bad state for a longer time hurting the decoding delay. On the other hand, the state holding times are shorter for a negatively correlated channel and state transitions are more frequent leading to a shorter decoding delay.

V. NUMERICAL RESULTS

In this section, we provide numerical results to substantiate our analysis of the RLNC scheme, both for the case of the time invariant channel model and the time correlated channel model. As a representative setup for the case of the time invariant channel model, we let the OFF probability of erasure channels p to be 0.1. Note that the broadcast capacity for this choice of p is $(1-p) = 0.9$. For the time correlated channel model, we choose $\alpha = \beta = 0.3$. The broadcast capacity for this choice is 0.5. We note that the scaling behavior of the throughput and decoding-delay do not change for any other choice of channel parameters. Our numerical results are presented under two different scenarios, the first focuses on confirming the phase transition of the throughput scaling, and the second focuses on substantiating the accuracy of our approximation for the mean decoding delay computed using extreme value theory.

Study 1) Phase transition: In this study, we explore the phase transition that is suggested by Theorem 1. To that end, Figure 4 depicts the (broadcast) throughput of RLNC in the actual system operation with increasing n for different types of scaling of k for the time invariant erasure channel. We see that this result is in perfect agreement with Theorem 1: when

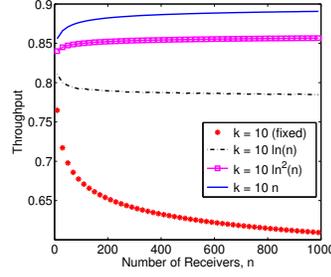

Fig. 4. Throughput behavior under different scalings of k with n when $p = 0.1$

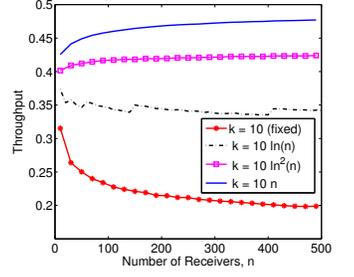

Fig. 5. Throughput behavior under different scalings of k with n when $\alpha = \beta = 0.3$ and capacity is 0.5.

$k = 10$ and therefore scales slower than $\ln(n)$, we see that the throughput decays towards zero; when $k = 10 \ln(n)$, i.e. $k = \Theta(\ln(n))$, the throughput converges to a constant level as suggested by Theorem 1; when $k = 10 \ln^2(n)$ or $10n$, i.e. $k = \omega(\ln(n))$, the throughput increases toward the broadcast capacity of 0.9.

Figure 5 depicts the (broadcast) throughput of RLNC in the actual system operation for the time correlated erasure channel model. Once again, we see that this result is in agreement with Theorem 1.

These two results also reveal that the convergence rate of the performance to the capacity may be increased by selecting a faster scaling of k with respect to n . Thus, Study 1 confirms the phase transition suggested by our analysis. The next study is aimed at studying the convergence of distribution of the decoding delay.

Study 2) Convergence in Distribution: Here, we consider the scaling $k = n$ and compare the probability density function (pdf) of standardized decoding delay $\frac{\tilde{U} - b_n}{a_n}$ (recall that $\tilde{U} = \frac{U - \mu(k)}{\sigma(k)}$) to that of the Gumbel distribution. We

can see from Figure 10, that for n equal to 1500 and 10,000, the distribution of the standardized decoding delay is well approximated by the Gumbel distribution. Next, we study the accuracy of our approximation for the mean decoding delay computed using extreme value theory.

Study 3) Approximate Mean Decoding Delay: Here, we consider two different scalings of k with respect to n , and compare the mean decoding-delay of the actual system to the approximate expression obtained using extreme value theory. In particular, we study the cases when $k = 50 \ln(n)$ and $k = n$.

First, we consider the case of time invariant channel model. Figure 6 depicts mean decoding-delay performance when $k = 50 \ln(n)$ of the actual system behavior together with the approximate mean obtained using extreme value theory. This demonstrates the accuracy of our approximation even for small values of n . We also see that a throughput of approximately 0.85 (see Figure 4) is achievable with this scaling, leading to a decoding delay that scales only logarithmically with the network size.

In comparison, Figure 7 depicts the mean decoding-delay of the actual system and approximate mean when $k = n$.

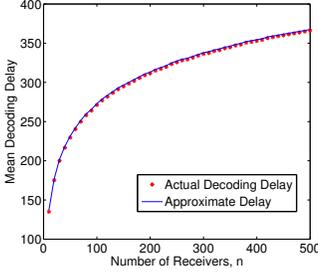

Fig. 6. Comparing Actual Mean Decoding Delay to Approximate Mean for $p = 0.1$ and $k = 50 \ln(n)$.

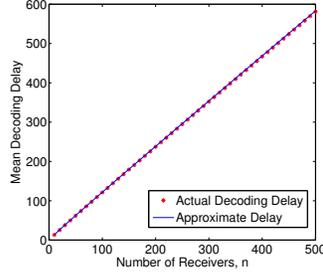

Fig. 7. Comparing Actual Mean Decoding Delay to Approximate Mean for $p = 0.1$ and $k = n$.

Again, we observe that our approximation is accurate and applicable to the actual system performance, as predicted. In this fast scaling scenario, we also observe that the throughput increases towards the capacity of 0.9 (see Figure 4) instead of converging to a constant level as in the case of scaling k as $\ln(n)$. Yet, this asymptotic optimality occurs at the cost of linearly increasing decoding-delay performance.

Next, we consider the case of time correlated channel

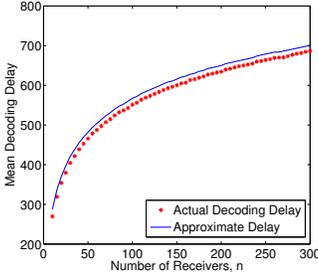

Fig. 8. Comparing Actual Mean Decoding Delay to Approximate Mean for $\alpha = \beta = 0.3$ and $k = 50 \ln(n)$.

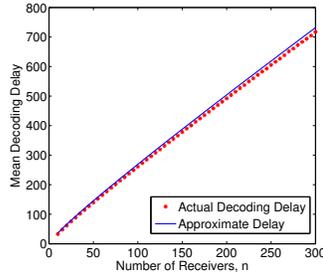

Fig. 9. Comparing Actual Mean Decoding Delay to Approximate Mean for $\alpha = \beta = 0.3$ and $k = n$.

model and compare the actual decoding delay of the RLNC scheme to the approximate expression in (30). Recall that the approximate decoding delay is derived under the assumption that the channel state of the system prior to the beginning of the current block transmission is $s = 1$. Nonetheless, we see, from Figures 8 and 9, that the approximation in (30) is an accurate characterization of the mean decoding delay of our system.

Next, we compare the broadcast throughput performance of RLNC for positively and negatively correlated channels with the same broadcast capacity of 0.5. From Figure 11, we see that the throughput performance is better for the case of negatively correlated channels ($\alpha = \beta = 0.7$) while it is worse for the case of positively correlated channels ($\alpha = \beta = 0.3$). Overall, these numerical studies collectively confirm the accuracy of estimating the mean decoding delay of RLNC using extreme value theory when k scales as function of n .

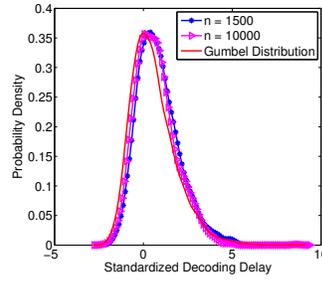

Fig. 10. Comparing the *pdf* of standardized decoding delay to Gumbel Distribution for $p = 0.1$ and $k = n$.

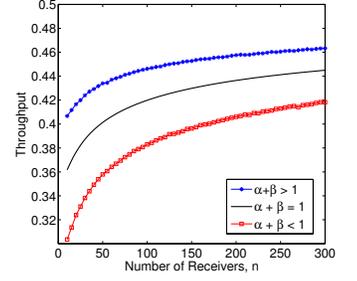

Fig. 11. Comparing the Rate of Convergence of Throughput when $k = n$ for three cases of Correlated Channels: 1) $\alpha = \beta = 0.7$, 2) $\alpha = \beta = 0.5$, and 3) $\alpha = \beta = 0.3$.

VI. EXTENSIONS

In this section, we discuss three important extensions of our analysis. First, we discuss how our analysis can be extended to LT codes. Next, we comment on the case where the channels are not independent across the users. Finally, we comment on the case of asymmetric channels where the channel of user i has a steady state erasure probability of p_i .

A. LT Codes

LT codes [15] are rateless codes designed such that receiving any $\nu_k(\delta_k) = k + O(\sqrt{k} \ln^2(k/\delta_k))$ encoded packets guarantees that the receiver can decode the original k packets with probability $(1 - \delta_k)$, where $\delta_k \in (0, 1)$. Note that by decreasing δ_k , and hence increasing $\nu_k(\delta_k)$, we can increase the probability of successfully decoding at the receiver. Assume that, under the coding strategy of LT codes, the source starts transmitting the next block only after all the receivers receive $\nu_k(\delta_k)$ encoded packets each of the current block. The analysis of Section IV can be repeated for the case of LT codes by replacing k with $\nu_k(\delta_k)$ in the derivation of the bounds on the inter-renewal interval $\mathbb{E}[W]$ and the computation of mean and variance of the decoding delay. However, in the case of LT codes, the users that receive more than $\nu_k(\delta_k)$ encoded packets have a higher probability of decoding than the other users. Therefore, we have to modify our definition of throughput as follows,

Definition 5 ((Broadcast) Throughput): We let $R_i[t]$ denote the number of packets successfully decoded by the user i in a total of t slots. Then, the (broadcast) throughput for a given n and k obtained using the LT coding scheme, denoted as $\eta(n, k)$, is the long-term average number of successfully transferred data packets to all n users. Hence, we have

$$\eta(n, k) = \lim_{t \rightarrow \infty} \frac{\sum_{i=1}^n R_i[t]}{nt}$$

We have the following result analogous to Theorem 1:

Theorem 2: Using the LT coding scheme, the broadcast throughput $\eta(n, k)$ of our system, when $\alpha, \beta > 0$, and $\alpha + \beta \neq 2$, can be characterized as follows,

- a) If $k = o(\ln(n))$, then

$$\lim_{n \rightarrow \infty} \eta(n, k) = 0.$$

b) If $k = \omega(\ln(n))$, and if

i) $\delta_k = \delta$ for all k , where $\delta \in (0, 1)$, then

$$\liminf_{n \rightarrow \infty} \eta(n, k) \geq (1-p)(1-\delta).$$

ii) $\ln(k/\delta_k) = o(k^{(1/4)})$, and $\lim_{k \rightarrow \infty} \delta_k = 0$, then

$$\lim_{n \rightarrow \infty} \eta(n, k) = (1-p).$$

c) Furthermore, if $k = \Theta(\ln(n))$, and if

i) $\delta_k = \delta$ for all k , where $\delta \in (0, 1)$, then

$$\liminf_{n \rightarrow \infty} \eta(n, k) \geq r(1-p)(1-\delta),$$

ii) $\ln(k/\delta_k) = o(k^{(1/4)})$, and $\lim_{k \rightarrow \infty} \delta_k = 0$, then

$$\liminf_{n \rightarrow \infty} \eta(n, k) \geq r(1-p),$$

for some $0 < r < 1$.

The above theorem is proved in a similar way to Theorem 1. Hence, we skip the detailed proof and instead provide a brief outline. The expected reward obtained by the source in one inter-renewal interval of the renewal process defined in Section IV-A is given by $\frac{\sum_{i=1}^n \mathbb{E}[R_i]}{n}$ where $\mathbb{E}[R_i]$ is reward obtained due to user i . Since each user can decode the current block with at least a probability of $(1 - \delta_k)$, we have that, $\mathbb{E}[R_i] \geq k\mathbb{E}[M](1 - \delta_k)$. Therefore, we have that, $\eta(n, k) \geq \frac{k\mathbb{E}[M](1 - \delta_k)}{\mathbb{E}[W]}$. Also, since the maximum reward that the source can obtain from each block transmission is k , we have that $\eta(n, k) \leq \frac{k\mathbb{E}[M]}{\mathbb{E}[W]}$. By replacing k with $\nu_k(\delta_k)$ in the upper and lower bounds obtained in Section IV-A for $\mathbb{E}[W]$, we obtain the corresponding bounds for the case of LT codes. Now, if δ_k is such that $\ln(k/\delta_k) = o(k^{(1/4)})$, then $\lim_{k \rightarrow \infty} \frac{\nu_k(\delta_k)}{k} = 1$. In this way, we can obtain the results in Theorem 2.

Recall that $(1-p)$ is an upper bound on the throughput achievable by any scheme. A choice of δ_k that satisfies the conditions 1) $\ln(k/\delta_k) = o(k^{(1/4)})$ and 2) $\lim_{k \rightarrow \infty} \delta_k = 0$ is given by $\delta_k = \frac{1}{\ln(k)}$. Hence, under the scaling regime of $k = \omega(\ln(n))$, this choice of δ_k would ensure that the throughput approaches $1-p$ as $n \rightarrow \infty$.

B. Dependent channel model

Next, consider the case of symmetric time-invariant channels that are dependent across the users. For all i , let $C_i[t] = 0$ with a probability p and $C_i[t] = 1$ with probability $(1-p)$. Lemma 1 holds true even when the random variables χ_i , $i = 1, \dots, n$ are dependent. However, Lemmas 2, 3 and 4 are not valid anymore. Nonetheless, we can show that if $k = \omega(\ln(n))$, then $\lim_{n \rightarrow \infty} \eta(n, k) = 1-p$ even when the user channels are dependent. Next, we prove this sufficient condition to achieve broadcast capacity.

Once again, we drop the superscript (j) in the following discussion. Let $\mu(k) = \frac{k}{1-p}$ and $\sigma^2(k) = k\frac{p}{(1-p)^2}$. Define $\tilde{Y}_i(k) = \frac{Y_i(k) - \mu(k)}{\sigma(k)}$. Note that U can be rewritten as follows,

$$U = \mu(k) + \sigma(k) \max_{1 \leq i \leq n} \tilde{Y}_i(k) \quad (32)$$

Consider the case when $k = f(n)\ln(n)$ for some function $f(n) > 0$. Note that in our analysis we treat k as a continuous function of n . This assumption does not seriously affect the analysis and can easily be relaxed. Choose $\tau = b\sqrt{\ln(n)}$ where b is a constant such that $0 < \tau \leq \sigma(k)\ln(\frac{1}{1-p})$. Such a τ lies within the radius of convergence of the m.g.f of $\tilde{Y}_1(k)$, which is then given by:

$$\begin{aligned} \mathbb{E}[e^{\tau\tilde{Y}_1(k)}] &= e^{\tau k/\sigma(k)} e^{-\tau\mu(k)/\sigma(k)} \left[\frac{1-p}{1-pe^{\tau/\sigma(k)}} \right]^k \\ &= \left[\frac{(1-p)e^{-b\sqrt{p}/\sqrt{f(n)}}}{1-pe^{b(1-p)/\sqrt{pf(n)}}} \right]^{f(n)\ln(n)} \end{aligned} \quad (33)$$

Now, using (13) with $\tau = b\sqrt{\ln(n)}$, and, (32), and (33), we can bound the expected decoding delay as follows:

$$\begin{aligned} \mathbb{E}[U] &\leq \mu(k) + \frac{\sigma(k)}{\tau} \left(\ln(n) + \ln \left(\mathbb{E}[e^{\tau\tilde{Y}_1(k)}] \right) \right) \\ &\leq \frac{\ln(n)}{1-p} f(n) \\ &\quad + \frac{\ln(n)\sqrt{f(n)p}}{b(1-p)} \left(1 + f(n) \ln \left(\frac{(1-p)e^{-b\sqrt{p}/\sqrt{f(n)}}}{1-pe^{b(1-p)/\sqrt{pf(n)}}} \right) \right), \end{aligned}$$

Hence, by using (4), the throughput can be bounded as follows:

$$\eta(n, k) = \frac{k}{\mathbb{E}[U]} \geq h(n)(1-p), \quad (34)$$

where (34) follows from (4), and $h(n)$ is given as

$$\frac{1}{h(n)} = 1 + \frac{\sqrt{p}}{b\sqrt{f(n)}} \left(1 + f(n) \ln \frac{(1-p)e^{-b\sqrt{p}/\sqrt{f(n)}}}{1-pe^{b(1-p)/\sqrt{pf(n)}}} \right).$$

First, let $f(n) = \hat{b}$ where $\hat{b} \geq 0$ is a constant independent of n . Then $h(n)$ is a constant independent of n with $h(n) < 1$ ($h(n)$ can be expressed explicitly in terms of b, \hat{b} and p). From (34), we see that the scaling regime of $k = \Theta(\ln(n))$ guarantees that $\liminf_{n \rightarrow \infty} \eta(n, k)$ is a non-vanishing fraction of the broadcast capacity $(1-p)$. Next, let $f(n)$ be such that $f(n) \rightarrow \infty$ as

$n \rightarrow \infty$. Then,

$$\begin{aligned}
& \lim_{n \rightarrow \infty} \frac{1}{h(n)} - 1 \\
&= \lim_{n \rightarrow \infty} \frac{\sqrt{p}}{b\sqrt{f(n)}} \left(1 + f(n) \ln \frac{(1-p)e^{-b\sqrt{p}/\sqrt{f(n)}}}{1 - pe^{b(1-p)/\sqrt{pf(n)}}} \right) \\
&= \lim_{n \rightarrow \infty} \frac{\sqrt{p}}{b} \sqrt{f(n)} \ln \frac{(1-p)e^{-b\sqrt{p}/\sqrt{f(n)}}}{1 - pe^{b(1-p)/\sqrt{pf(n)}}} \\
&= \lim_{n \rightarrow \infty} \frac{-\sqrt{p}}{b} \sqrt{f(n)} \left(1 - \frac{(1-p)e^{-b\sqrt{p}/\sqrt{f(n)}}}{1 - pe^{b(1-p)/\sqrt{pf(n)}}} \right) \\
&= \frac{-\sqrt{p}}{b(1-p)} \lim_{n \rightarrow \infty} \sqrt{f(n)} \left(1 - pe^{b(1-p)/\sqrt{pf(n)}} \right. \\
&\quad \left. - (1-p)e^{-b\sqrt{p}/\sqrt{f(n)}} \right) \\
&= \frac{-\sqrt{p}}{b(1-p)} \lim_{n \rightarrow \infty} \left(-\frac{b\sqrt{p}(1-p)}{\sqrt{f(n)}} e^{b(1-p)/\sqrt{pf(n)}} \right. \\
&\quad \left. - \frac{-b\sqrt{p}(1-p)}{\sqrt{f(n)}} e^{-b\sqrt{p}/\sqrt{f(n)}} \right) \tag{iii} \\
&= 0,
\end{aligned}$$

where (iii) is obtained using *L'Hôpital's* rule.

Hence, we have $h(n) \rightarrow 1$ and $\eta(n, k) \rightarrow (1-p)$ as $n \rightarrow \infty$ proving it is sufficient that $k = \omega(\ln(n))$ to achieve the broadcast capacity $(1-p)$.

We can easily see that it is no longer true that if $k = o(\ln(n))$, then $\lim_{n \rightarrow \infty} \eta(n, k) = 0$. For example, consider the trivial case of perfectly correlated user channels. Then the system reduces to the case where there is a single user channel and hence, the throughput, $\eta(n, k)$, of this system does not depend on n . Also, the sufficient condition of $k = \omega(\ln(n))$ is unnecessary in this trivial case as it is always true that $\eta(n, k) \rightarrow (1-p)$ as $k \rightarrow \infty$. Although the sufficiency condition appears to be a rather weak condition for the trivial example of perfectly correlated channels, it is still useful when the system has weak correlations.

C. Asymmetric channel model

Consider the case of asymmetric time-invariant channels where $C_i[t] = 0$ with a probability p_i and $C_i[t] = 1$ with probability $(1-p_i)$. The channels of all users are assumed to be independent of each other. Suppose that $p_0 = \sup_i p_i$ exists. Then the broadcast capacity of our system is $(1-p_0)$. Let $\mathbb{E}[U_1]$ and $\eta_1(n, k)$ denote the mean decoding delay and throughput of this system. We can compare this system with the symmetric system with erasure probabilities p_0 . Let $\mathbb{E}[U_0]$ and $\eta_0(n, k)$ denote the mean decoding delay and throughput of the symmetric system. By comparing the cumulative distributions of the decoding delay of the two systems, we can show that $\mathbb{E}[U_1] \leq \mathbb{E}[U_0]$. Consequently, $\eta_0(n, k) \leq \eta_1(n, k) \leq 1-p_0$. From Theorem 1, we have that, if $k = \omega(\ln(n))$, then $\lim_{n \rightarrow \infty} \eta_0(n, k) = 1-p_0$ and hence, $\lim_{n \rightarrow \infty} \eta_1(n, k) = 1-p_0$.

The case of asymmetric time-correlated channels is technically challenging since it is not easy to obtain a closed form expression for the mean decoding delay as in the case of time-invariant channels.

VII. CONCLUSION

We have investigated the throughput and decoding delay performance of RLNC in a wireless broadcast setting as the coding window size k scales with the number of receivers n for a time correlated erasure channel model. We noted that the broadcast throughput of RLNC vanishes for any fixed k as the system size increases. Hence, it is important to understand the scaling of k as a function of n that will guarantee a non-vanishing throughput.

Our analysis revealed a phase transition in the performance of our system, namely, if k increases slower than $\ln(n)$, the throughput goes to zero as n increases. However, on increasing k faster than $\ln(n)$, the throughput approaches the maximum achievable broadcast throughput of $(1-p)$. Also, $k = \Theta(\ln(n))$ ensures a constant fraction of the maximum achievable broadcast throughput for the our system. Further, we have provided approximate expressions for the mean decoding delay under the scaling regime of $k = \omega(\ln(n))$ using extreme value theory. We have shown through numerical results that our approximation is accurate even for small values of n . We have also shown that our analysis can be extended to other rateless block coding schemes such as the LT codes. In particular, by choosing δ_k such that $\lim_{k \rightarrow \infty} \delta_k = 0$, we see that under the scaling regime of $k = \omega(\ln(n))$, LT codes achieve the broadcast throughput of $(1-p)$ as $n \rightarrow \infty$. Further, we commented on the extension of our analysis for the cases of dependent channels across users, and asymmetric channel model.

APPENDIX

We first state the optional stopping theorem to be used later to prove Lemma 3.

Theorem 3: (cf. [10], Theorem 6.2.2, p.300) Let $\{Z_n, n \geq 1\}$ be a martingale process and let M be a stopping time with respect to the filtration $\{\mathcal{F}_n\}$. If $\mathbb{E}[M] < \infty$, and there exists a constant $c < \infty$ such that $\mathbb{E}[|Z_{n+1} - Z_n| | \mathcal{F}_n] < c$, then the process stopped at M , i.e.,

$$\bar{Z}_n = \begin{cases} Z_n & \text{if } n \leq M \\ Z_M & \text{if } n > M \end{cases}$$

is also a martingale and $\mathbb{E}[Z_M] = \mathbb{E}[Z_n]$.

A. Proof of Lemma 2

Proof: We note that we cannot apply Lemma 1 here since for $h = 1$, i.e, the first linear combination in any block transmission, the random variables $X_{ih}^{(j)}$, for $i = 1, \dots, n$, are not identically distributed. Recall that β is the transition probability from channel state off to channel state ON (see

Figure 2). Fix a $\tau_0 < \ln(\frac{1}{1-\beta})$. Then,

$$\begin{aligned} \mathbb{E} \left[e^{\tau_0 X_{ih}^{(j)}} \right] &= \mathbb{E} \left[e^{\tau_0 X_{ih}^{(j)}} | B_i^{(j)} = 0 \right] \mathbb{P}(B_i^{(j)} = 0) \\ &\quad + \mathbb{E} \left[e^{\tau_0 X_{ih}^{(j)}} | B_i^{(j)} = 1 \right] \mathbb{P}(B_i^{(j)} = 1) \\ &= \left[e^{2\tau_0} \beta \sum_{v=0}^{\infty} e^{v\tau_0} (1-\beta)^v \right] \mathbb{P}(B_i^{(j)} = 0) \\ &\quad + e^{\tau_0} \mathbb{P}(B_i^{(j)} = 1) \\ &< \infty. \end{aligned}$$

$\sum_{v=0}^{\infty} e^{v\tau_0} (1-\beta)^v < \infty$ because $e^{\tau_0} (1-\beta) < 1$ by our choice of τ_0 and hence, $\mathbb{E} \left[e^{\tau_0 X_{ih}^{(j)}} \right]$ exists and is finite.

Let $B_i^{(j)}$ be the channel state of the i^{th} user at the beginning of the j^{th} block transmission. Let $\mu_0 = \max_{s_i \in \{0,1\}} \mathbb{E} \left[e^{\tau_0 X_{ih}^{(j)}} | B_i^{(j)} = s_i \right]$. Now, since the channel state of any user is independent of other users' channels, $\mathbb{E} \left[e^{\tau_0 X_{ih}^{(j)}} | \mathbf{B}^{(j)} = \mathbf{s} \right] = \mathbb{E} \left[e^{\tau_0 X_{ih}^{(j)}} | B_i^{(j)} = s_i \right] \leq \mu_0$ for all i, j , and, $h \in \{1, \dots, k\}$. Hence, we have,

$$\begin{aligned} &\mathbb{E} \left[\max_{1 \leq i \leq n} X_{ih}^{(j)} | \mathbf{B}^{(j)} = \mathbf{s} \right] \\ &= \mathbb{E} \left[\frac{1}{\tau_0} \ln \left(\max_{1 \leq i \leq n} e^{\tau_0 X_{ih}^{(j)}} \right) | \mathbf{B}^{(j)} = \mathbf{s} \right] \\ &\leq \frac{1}{\tau_0} \ln \left(\mathbb{E} \left[e^{\tau_0 X_{1h}^{(j)}} + \dots + e^{\tau_0 X_{nh}^{(j)}} | \mathbf{B}^{(j)} = \mathbf{s} \right] \right) \\ &= \frac{1}{\tau_0} \ln \left(\sum_{i=1}^n \mathbb{E} \left[e^{\tau_0 X_{ih}^{(j)}} | \mathbf{B}^{(j)} = \mathbf{s} \right] \right) \\ &\leq \frac{1}{\tau_0} (\ln(n) + \ln(\mu_0)) \end{aligned}$$

B. Proof of Lemma 3

Proof: Let $\xi^{(j)} = \max_{1 \leq i \leq n} X_{i1}^{(j)}$. Recall that $\mathbf{E}^{(j)} \in \mathcal{S}^n$ is the channel state of the system at the end of the j^{th} block transmission, where $\mathcal{S} = \{0, 1\}$. Let \mathcal{F}_j be the smallest σ -field of events containing the σ -fields generated by the random variables $\{X_{ih}^{(1)}, \dots, X_{ih}^{(j)}, i = 1, \dots, n, h = 1, \dots, k\}$ and $\mathbf{E}^{(1)}, \dots, \mathbf{E}^{(j)}$. Let $Z_0 = 0$. Define $Z^{(m)} = \sum_{j=1}^m (\xi^{(j)} - \mu^{(j)})$ where $\mu^{(j)} = \mathbb{E}[\xi^{(j)} | \mathcal{F}_{j-1}]$. Also,

$$\begin{aligned} \mu^{(j)} &= \mathbb{E}[\xi^{(j)} | \mathcal{F}_{j-1}] \\ &= \sum_{\mathbf{s} \in \mathcal{S}} \mathbb{E}[\xi^{(j)} | \mathbf{B}^{(j)} = \mathbf{s}, \mathcal{F}_{j-1}] \mathbb{P}(\mathbf{B}^{(j)} = \mathbf{s} | \mathcal{F}_{j-1}) \\ &= \sum_{\mathbf{s} \in \mathcal{S}} \mathbb{E}[\xi^{(j)} | \mathbf{B}^{(j)} = \mathbf{s}] \mathbb{P}(\mathbf{B}^{(j)} = \mathbf{s} | \mathcal{F}_{j-1}) \\ &\leq \mu, \end{aligned}$$

where the last inequality follows from Lemma 2. Then $\mathbb{E}[\xi^{(j)}] = \mathbb{E}[\mu^{(j)}] \leq \mu$. We have that $\{Z^{(m)}\}$ is a martingale by definition. Also, M is a stopping time with respect to the

filtration $\{\mathcal{F}_j\}$ with $\mathbb{E}[M] < \infty$ and

$$\begin{aligned} \mathbb{E}[Z^{(m+1)} - Z^{(m)} | \mathcal{F}_m] &= \mathbb{E}[\xi^{(m+1)} - \mu^{(m+1)} | \mathcal{F}_m] \\ &\leq \mathbb{E}[\xi^{(m+1)} | \mathcal{F}_m] + \mu^{(m+1)} \\ &= 2\mu^{(m+1)} \leq 2\mu < \infty. \end{aligned}$$

Hence, using the optional stopping theorem (Theorem 3), we have $\mathbb{E}[Z^{(M)}] = \mathbb{E}[Z^{(1)}] = 0$. Therefore,

$$\begin{aligned} 0 = \mathbb{E}[Z^{(M)}] &= \mathbb{E} \left[\sum_{j=1}^M \xi^{(j)} \right] - \mathbb{E} \left[\sum_{j=1}^M \mu^{(j)} \right] \\ &\geq \mathbb{E} \left[\sum_{j=1}^M \xi^{(j)} \right] - \mathbb{E}[M\mu]. \end{aligned}$$

Thus, we have $\mathbb{E} \left[\sum_{j=1}^M \xi^{(j)} \right] \leq \mathbb{E}[M]\mu$ as required. \blacksquare

C. Proof of Lemma 4

Proof: We have that $\mathbb{P}(X_{i2}^{(j)} = 1) = 1 - \alpha$ and $\mathbb{P}(X_{i2}^{(j)} = u) = \alpha\beta(1-\beta)^{u-2}$, for all $u \geq 2$. Hence,

$$\begin{aligned} \mathbb{P}(X_{i2}^{(j)} \leq u) &= (1-\alpha) + \sum_{v=2}^u \alpha\beta(1-\beta)^{v-2} \\ &= 1 - \alpha(1-\beta)^{u-1} \end{aligned}$$

Therefore,

$$\mathbb{P} \left(\max_{1 \leq i \leq n} X_{i2}^{(j)} \leq u \right) = (1 - \alpha(1-\beta)^{u-1})^n \quad \forall u \geq 1,$$

and $\mathbb{E} \left[\max_{1 \leq i \leq n} X_{i2}^{(j)} \right]$ is given as

$$\begin{aligned} \mathbb{E} \left[\max_{1 \leq i \leq n} X_{i2}^{(j)} \right] &= 1 + \sum_{u=1}^{\infty} \left(1 - \left[1 - \alpha e^{-\lambda(u-1)} \right]^n \right) \\ &\geq 1 + \int_0^{\infty} (1 - (1 - \alpha e^{-\lambda x})^n) dx \end{aligned}$$

By setting $w = 1 - \alpha e^{-\lambda x} \in [0, 1)$ in the above integral, we have the following inequalities,

$$\begin{aligned} \mathbb{E} \left[\max_{1 \leq i \leq n} X_{i2}^{(j)} \right] &\geq 1 + \int_{1-\alpha}^1 \frac{1-w^n}{\lambda(1-w)} dw \\ &= 1 + \frac{1}{\lambda} \int_{1-\alpha}^1 \sum_{z=0}^{n-1} w^z dw \\ &= 1 + \frac{1}{\lambda} \sum_{z=0}^{n-1} \int_{1-\alpha}^1 w^z dw \\ &= 1 + \frac{1}{\lambda} \sum_{z=0}^{n-1} \frac{1}{z+1} - \frac{1}{\lambda} \sum_{z=0}^{n-1} \frac{(1-\alpha)^{z+1}}{z+1} \\ &\geq 1 + \frac{1}{\lambda} \sum_{z=0}^{n-1} \frac{1}{z+1} - \frac{1}{\lambda} \sum_{z=0}^{n-1} \frac{1-\alpha}{z+1} \\ &\geq 1 + \frac{\alpha}{\lambda} [\ln(n) + \gamma]. \end{aligned}$$

B. T. Swapna received her B.Tech and M.Tech. degrees in Electrical Engineering from the Indian Institute of Technology, Madras, India, in 2008, and is currently pursuing the Ph.D. degree in Electrical and Computer engineering at The Ohio State University, Columbus, OH, USA. Her research interests are in the areas of communication networks and social and information networks.

Atilla Eryilmaz (S'00-M'06) received his B.S. degree in Electrical and Electronics Engineering from Boğaziçi University, Istanbul, in 1999, and the M.S. and Ph.D. degrees in Electrical and Computer Engineering from the University of Illinois at Urbana-Champaign in 2001 and 2005, respectively. Between 2005 and 2007, he worked as a Postdoctoral Associate at the Laboratory for Information and Decision Systems at the Massachusetts Institute of Technology. He is currently an Assistant Professor of Electrical and Computer Engineering at The Ohio State University. Dr. Eryilmaz's research interests include design and analysis for complex networked systems, optimal control of stochastic networks, optimization theory, distributed algorithms, pricing in networked systems, and information theory. He received the NSF-CAREER and the Lumley Research Awards in 2010.

Ness B. Shroff (S'91-M'93-SM'01-F'07) received his Ph.D. degree in Electrical Engineering from Columbia University in 1994. He joined Purdue university immediately thereafter as an Assistant Professor in the school of Electrical and Computer Engineering. At Purdue, he became Full Professor of ECE in 2003 and director of CWSA in 2004, a university-wide center on wireless systems and applications. In July 2007, he joined The Ohio State University, where he holds the Ohio Eminent Scholar endowed chair in Networking and Communications, in the departments of ECE and CSE. From 2009-2012, he served as a Guest Chaired professor of Wireless Communications at Tsinghua University, Beijing, China, and currently holds an honorary Guest professor at Shanghai Jiaotong University in China. His research interests span the areas of communication, social, and cyberphysical networks. He is especially interested in fundamental problems in the design, control, performance, pricing, and security of these networks. Dr. Shroff is a past editor for IEEE/ACM Trans. on Networking and the IEEE Communication Letters. He currently serves on the editorial board of the Computer Networks Journal, IEEE Network Magazine, and the Networking Science journal. He has chaired various conferences and workshops, and co-organized workshops for the NSF to chart the future of communication networks. Dr. Shroff is a Fellow of the IEEE and an NSF CAREER awardee. He has received numerous best paper awards for his research, e.g., at IEEE INFOCOM 2008, IEEE INFOCOM 2006, Journal of Communication and Networking 2005, Computer Networks 2003 (two of his papers also received runner-up awards at IEEE INFOCOM 2005 and INFOCOM 2013), and also student best paper awards (from all papers whose first author is a student) at IEEE WiOPT 2013, IEEE WiOPT 2012 and IEEE IWQoS 2006.
